## ABSTRACT

A number of concurrent, relaxed priority queues have recently been proposed and implemented. Results are commonly reported for a *throughput benchmark* that uses a uniform distribution of keys drawn from a large integer range, and mostly for single systems. We have conducted more extensive benchmarking of three recent, relaxed priority queues on four different types of systems with different key ranges and distributions. While we can show superior throughput and scalability for our own *k*-LSM priority queue for the uniform key distribution, the picture changes drastically for other distributions, both with respect to achieved throughput and relative merit of the priority queues. The throughput benchmark alone is thus not sufficient to characterize the performance of concurrent priority queues. Our benchmark code and *k*-LSM priority queue are publicly available to foster future comparison.

## 1. CONCURRENT PRIORITY QUEUES

Due to the increasing number of processors in modern computer systems, there is significant interest in concurrent data structures with scalable performance that goes beyond a few dozen processor-cores. However, data structures (e.g., priority queues) with strict sequential semantics often present (inherent) bottlenecks (e.g., the delete_min operation) to scalability, which motivates weaker correctness conditions or data structures with relaxed semantics (e.g., one of the smallest $k$ items for some $k$ allowed to be deleted). Applications can often accomodate such relaxations, and in many such cases (discrete event simulation, shortest path algorithms, branch-and-bound), the priority queue is a key data structure.

Many lock-free designs have been based on Skiplists [5, 7, 8]. In contrast, the recently proposed, relaxed *k*-LSM priority queue [9] is based on a deterministic Log-Structured Merge-Tree (LSM), and combines an efficient thread-local variant for scalability with a shared, relaxed variant for semantic guarantees. The *k*-LSM priority queue is lock-free, linearizable, and provides configurable guarantees of delete_min returning one of the $kP$ smallest items, where $k$ is a configuration parameter and $P$ the number of cores (threads). The SprayList [1] uses a lock-free Skiplist, and allows delete_min to remove a random element from the $O(P \log^3 P)$ items at the head of the list. MultiQueues [6] randomly spread both insertions and deletions over $cP$ local priority queues, each protected by a lock, with tuning parameter $c$, but gives no obvious guarantees on the order of deleted elements.

## 2. A CONFIGURABLE BENCHMARK

Priority queue performance is often measured by counting the number of insert and delete_min operations that can be performed in a given amount of time, i.e., the *throughput*, which would ideally increase linearly with the number of threads. Like recent studies [1, 5, 7, 8, 9], we also measure throughput, but additionally we experiment with different *workloads*: (a) *uniform*, where each thread performs 50% insertions and 50% deletions, randomly chosen, (b) *split*, where half the threads perform only insertions, and the other half only deletions; and (integer) *key distributions*: (a) *uniform*, where keys are drawn uniformly at random from the range of 32-bit, 16-bit, or 8-bit integers, and (b) *ascending (descending)*, where keys are drawn from a 10-bit integer range which is shifted upwards (downwards) at each operation (plus/minus one).

Queues are prefilled with $10^6$ elements with keys taken from the chosen distribution. This benchmark provides more scope for investigating locality (split workload), distribution and range sensitivity. The benchmark could be parameterized further [2] to provide for wider synthetic workloads, e.g., sorting as in [4]. To some extent, our ascending/descending distributions correspond to the *hold model* advocated in [3].

For relaxed priority queues, it is as important to characterize the deviation from strict priority queue behavior, also for verifying whether claimed relaxation bounds hold. We have implemented a rank error benchmark as in [6], where the rank of an item is its position within the priority queue as it is deleted.

## 3. EXPERIMENTAL RESULTS

We have benchmarked variants of the *k*-LSM priority queue [9] with different relaxation settings (klsm128, klsm256, klsm4096) against a Skiplist based queue [5] (linden), the

Table 1: `mars`: Rank error, uniform workload and keys.

MultiQueue [6] (`multiq`) and the SprayList [1] (`spray`). As a baseline we have used a sequential heap protected by a lock (`globallock`). The benchmarks ran on four different machines, but we give only results from an 80-core Intel Xeon E7-8850 2 GHz system (`mars`) here (without hyperthreading); see the appendix for full details and results on all machines. Each benchmark is executed 30 times, and we report on the mean values and confidence intervals. Our benchmark code can be found at https://github.com/klsmpq/klsm.

Figure 1 compares the seven priority queue variants under *uniform workload, uniform keys*. The $k$-LSM variant with $k = 4096$ exhibits superior scalability and throughput of more than 300 million operations per second (MOps/s), and vastly outperforms the other priority queues. Changing to a *split workload* and *ascending keys*, this picture changes dramatically, as shown in Figure 2 where the throughput drops by a factor of 10. Here `multiq` performs best, also in terms of scalability, surprisingly closely followed by `linden`. Restricting the key range likewise dramatically reduces the throughput, but the $k$-LSM performs better in this case, (Figure 3). In the latter two benchmark configurations, the SprayList code was not stable and it was not possible to gather results. Similar behavior and sensitivity can be observed for the other three machines. Hyperthreading only in rare cases leads to a throughput increase. Overall, `multiq` delivers the most consistent performance.

The rank error results in Table 1 for the uniform workload, uniform key situation show that `delete_min` for all queues return keys that are not far from the minimum, much better than the the worst-case analyses predict.

# APPENDIX

This appendix contains the full set of experimental results and details on the experimental setup. We briefly recapitulate the main three priority queue implementations, and describe the benchmarks in more detail. The remainder are our current results from the four available machines.

## A. CONCURRENT, RELAXED PRIORITY QUEUES

The priority queues considered here support two operations on key-value pairs, namely:

- `insert`, which inserts a key-value pair into the priority queue, and

- `delete_min`, which removes a key-value pair with a smallest key and copies the corresponding value into a given location.

Concurrent priority queues so far neither support operations on specific key-value pairs, like for instance `decrease_key` as needed for asymptotically efficient single-source shortest path algorithms, nor operations on the queues as a whole like `meld`.

A *linearizable*, *strict* priority queue imposes a real time order on priority queue operations, and in such an order each `delete_min` must return a least key-value pair. Relaxed consistency conditions like *quasi-linearizability* allow some non-determinism by accepting runs that are some bounded distance away from a strict, linear order [1] as correct. Recently, an even weaker conditions called *local linearizability* was proposed [8], but this may be too weak to be useful for priority queues. On the other hand, relaxed priority queue semantics relax the sequential priority queue semantics to allow that one of the $k$ smallest keys is returned, for some value $k$, at the `delete_min` operation [25, 26]. Such relaxed priority queues are considered here. Presumably, the better and the more precisely $k$ can be controlled, the better for the applications.

## B. THE $K$-LSM PRIORITY QUEUE

The $k$-LSM [7, 26] is a lock-free, linearizable, relaxed priority queue consisting of a global component called the Shared LSM (SLSM), and a thread-local component called the Distributed LSM (DLSM). As their names imply, both the SLSM and DLSM are based on the LSM (Log-Structured Merge-Tree) [18] data structure. The LSM was first introduced to the database community in 1996 and later reinvented independently by Wimmer driven by the requirements of relaxed, concurrent priority queues [25]. Both the SLSM and the DLSM may be used as standalone priority queues, but have complementary advantages and disadvantages which can be balanced against each other by their composition.

The LSM consists of a logarithmic number of sorted arrays (called blocks) storing key-value containers (items). Blocks have capacities $C = 2^i$ and capacities within the LSM are distinct. A block with capacity $C$ must contain more than $\frac{C}{2}$ and at most $C$ items. Insertions initially add a new singleton block to the LSM, and then merge blocks with identical capacities until all block capacities within the LSM are once again distinct. Deletions simply return the smallest of all blocks' minimal item. It is easy to see that both insertions and deletions can be supported in $O(\log n)$ operations where $n$ is the number of items in the LSM.

The DLSM is a distributed data structure containing a single thread-local LSM per thread. Operations on the DLSM are essentially embarrassingly parallel, since inter-thread communication occurs only when a deletion finds the local LSM empty, and then attempts to copy another thread's items. Items returned by `delete_min` are guaranteed to be minimal on the current thread.

The SLSM consists of a single global, centralized LSM, together with a corresponding range of items called the pivot range. The SLSM's pivot range depicts a subset of the $k+1$ smallest items (where $k$ is the relaxation parameter). Deletions randomly choose an item from this range, and thus are allowed to skip at most $k$ items.

Finally, the $k$-LSM itself is a very simple data structure: it contains a DLSM, limited to a maximum capacity of $k$ per thread; and a SLSM with a pivot range containing at most $k+1$ of its smallest items. Items are initially inserted into the local DLSM. When its capacity overflows, its largest block is batch-inserted into the SLSM. Deletions simply peek at both the DLSM and SLSM, and return the smaller item. Since deletions from the DLSM skip at most $k(P-1)$ items (where $P$ is the number of threads) and deletions from the SLSM skip at most $k$ items, $k$-LSM deletions skip a maximum of $kP$ items in total.

We implemented the $k$-LSM using the C++11 memory model. A memory model determines the order in which changes to memory locations by one thread become visible to other threads; for instance, usage of the the `std::atomic` type together with its `load()` and `store()` operations ensures portable multithreaded behavior across different architectures. It is possible to vary the strictness of provided guarantees between sequential consistency (on the strict end) and relaxed behavior (guaranteeing only atomicity).

In our implementation, we extensively use the previously mentioned `std::atomic` type together with its `load`, `store`, `fetch_add`, and `compare_exchange_strong` operations. When possible, we explicitly use relaxed memory ordering as it is the potentially most efficient (and weakest) of all memory ordering types, requiring only atomicity.

Our implementation, consisting of a standalone $k$-LSM as well as our parameterizable benchmark, is publicly available at https://github.com/klsmpq/klsm, and desribed in detail in [7].

## C. ALGORITHMS

Our benchmarks compare the following algorithms:

**Globallock** (`globallock`). A simple, standardized sequential priority queue implementation protected by a global lock is used to establish a baseline for acceptable performance. We use the simple priority queue implementation (`std::priority_queue`) provided by the C++ Standard Library (STL) [11].

**Linden** (`linden`). The Lindén and Jonsson priority queue [15] is currently one of the most efficient Skiplist-based designs, improving upon the performance of previous similar data structures [9, 22, 24] by up to a factor of two. It is lock-free and linearizable, but has strict semantics, i.e., deletions must return the minimal item in some real-time order.

**SprayList** (`spray`). This relaxed priority queue is based on the lock-free Fraser Skiplist [5]. Deletions use a random-walk method in order to return one of the $O(P \log^3 P)$ small-

est items, where $P$ is the number of threads [2].

**MultiQueue** (`multiq`). The MultiQueue is a recent design by Rihani, Sanders, and Dementiev [20] and consists of $cP$ arbitrary priority queues, where $c$ is a tuning parameter (set to 4 in our benchmarks) and $P$ is the number of threads; our benchmark again uses the simple sequential priority queue (`std::priority_queue`) provided by the STL [11], each protected by a lock. Items are inserted into a random priority queue, while deletions return the minimal item of two randomly selected queues. So far, no complete analysis of its semantic bounds exists.

$k$-**LSM** (`klsm128`, `klsm256`, `klsm4096`). We evaluate several instantiations of the $k$-LSM with varying degrees of relaxation, ranging from medium ($k \in \{128, 256\}$) to high relaxation ($k = 4096$). Results for low relaxation ($k = 16$) are not shown since its behavior closely mimics the Lindén and Jonsson priority queue.

Unfortunately, we were not able to measure every algorithm on each machine. The `linden` and `spray` priority queues require libraries not present on `ceres` and `pluto`. The SprayList implementation also turned out to be unstable in our experiments, crashing under most circumstances outside the uniform workload, uniform key distribution benchmark.

## D.   OTHER PRIORITY QUEUES

The Hunt et al. priority queue [10] is an early concurrent design. It is based on a Heap structure and attempts to minimize lock contention between threads by a) adding per-node locks, b) spreading subsequent insertions through a bit-reversal technique, and c) letting insertions traverse bottom-up in order to minimize conflicts with top-down deletions. It has been shown to perform well compared to other efforts of the time; however, it is easily outperformed by more modern designs.

Shavit and Lotan were the first to propose the use of Skiplists for priority queues [15]. Their initial locking implementation [22] builds on Pugh's concurrent Skiplist [19], which uses one lock per node per level. Herlihy and Shavit [9] later described and implemented a lock-free, quiescently consistent version of this idea in Java.

Sundell and Tsigas invented the first lock-free concurrent priority queue in 2003 [24]. Benchmarks show their queue performing noticeably better than both locking queues by Shavit and Lotan and Hunt et al., and slightly better than a priority queue consisting of a Skiplist protected by a single global lock.

Mounds [16, 17] is a recent concurrent priority queue design based on a tree of sorted lists. Liu and Spear provide two variants of their data structure; one of them is lock-based, while the other is lock-free and relies on the Double-Compare-And-Swap (DCAS) instruction, which is not available natively on most current processors.

One of the latest strict priority queues of interest, called the Chunk-Based Priority Queue (CBPQ), was presented recently in the dissertation of Braginsky [3]. It is primarily based on two main ideas: the chunk linked list [4] replaces Skiplists and heaps as the backing data structure, and use of the more efficient Fetch-And-Add (FAA) instruction is preferred over the Compare-And-Swap (CAS) instruction. Benchmarks compare the CBPQ against the Lindén and Jonsson queue and lock-free as well as lock-based versions of the Mound priority queue [16] for different workloads. The

CBPQ clearly outperforms the other queues in mixed workloads (50% insertions, 50% insertions) and deletion workloads, and exhibits similar behavior as the Lindén and Jonsson queue in insertion workloads, where Mounds are dominant.

## E.   MACHINES

The benchmarks were executed on four machines:

- `mars`, an 80-core (8x10 cores) Intel Xeon E7-8850 at 2 GHz with 1 TB of RAM main memory, and 32 KB L1, 256 KB L2, 24 MB L3 cache, respectively. `mars` has 2-way hardware hyperthreading.

- `saturn`, a 48-core machine with 4 AMD Opteron 6168 processors with 12 cores each, clocked at 1.9 GHz, and 125 GB RAM main memory, and 64 KB of L1, 512 KB of L2, and 5 MB of L3 cache, respectively. The AMD processor does not support hyperthreading.

- `ceres`, a 64-core SPARCv9-based machine with 4 processors of 16 cores each. Cores are clocked at 3.6 GHz and have 8-way hardware hyperthreading. Main memory is 1 TB RAM, and cache is 16 KB L1, 128 KB L2, and 8 MB L3, respectively.

- `pluto`, a 61-core Intel Xeon Phi processor clocked at 1.2 GHz with 4-way hardware hyperthreading. Main memory is 15 GB RAM, and cache 32 KB L1, 512 KB L2, respectively.

All applications are compiled using `gcc`, when possible: version `5.2.1` on `mars` and `saturn`, and version `4.8.2` on `ceres`. We use optimization level of `-O3` and enable link-time optimizations using `-flto`. Cross-compilation for the Intel Xeon Phi on `pluto` is done using Intel's `icc 14.0.2`. No further optimizations were performed, in particular vectorization was entirely delegated to the compiler, which probably leaves the Xeon Phi `pluto` at a disadvantage. On the other hand, all implementations are treated similarly.

## F.   BENCHMARKS

Our performance benchmarks are (currently) based on *throughput*, i.e., how many operations (insertions and deletions combined) complete within a certain timeframe. We prefill priority queues with $10^6$ elements prior the benchmark, and then measure throughput for 10 seconds, finally reporting on the number of operations performed per second. This metric and a roughly similar setup is used in much recent work [2, 15, 22, 24, 26]. Alternatively, a number of queue operations could be prescribed, and the time (latency) for this number and mix of operations measured.

The behavior of our throughput benchmark is controlled by the two parameters *workload* and *key distribution*. The workload may be

- *uniform*, meaning that each thread executes a roughly equal amount of insertions and deletions,

- *split*, meaning that half the threads insert, while the other half delete, or

- *alternating*, in which each thread strictly alternates between insertions and deletions.

The key distribution controls how keys are generated for inserted key-value pairs, and my may be either

- *uniform* with keys chosen uniformly at random from some range of integers (we have used 32-, 16-, and 8-bit ranges), or

- *ascending* or *descending*, meaning that a uniformly chosen key from a 10-bit integer range ascends or descends over time by adding or subtracting the chosen key to the operation number.

We would like to supply a parameterized benchmark similar to the Synchrobench framework of Gramoli [6] with the following orthogonal parameters:

- *Key type*: integer, floating point, possibly complex type from some ordered set (here, we have experimented with integers only).

- *Key base range*, which is the range from which the random component of the next key is chosen (here, we have used 32-, 16-, 10- and 8-bit ranges).

- *Key distribution*, the distribution of keys within their base range (here, we have used only uniform distributions, but others, e.g., as in [12], are also possible).

- *Key dependency* switch (none, ascending, descending), which determines whether the next key for a thread is dependent on the key of the last deleted element by the thread. A dependent key is formed by adding or subtracting the randomly generated base key to the key of the last deleted item (we have experimented with dependent keys where the next key is formed by adding to or subtracting from the operation number).

- *Operation distribution*: insertions and deletions are chosen randomly with a prescribed probability of an operation being an insert (we have experimented with 50% insertions so that the queues remain in a steady state).

- Alternatively, an *operation batch size* can be set to alternate between batches of insertions and deletions (we have experimented with strictly alternating insertions and deletions).

- *Workload* determines the fraction of threads that perform insertions and the fraction of threads that perform deletions (we have experimented with uniform and split workloads, where in the latter half the threads perform the insertions and the other half the deletions).

- *Prefill* determines the number of items put in the queue before the time measurement starts; prefilling is done according to the workload and key distribution.

- *Throughput/latency* switch, where for throughput a duration (time limit) is specified and for latency the total number of operations.

- *Repetition count* and other statistic requirements.

For instance, giving an operation batch size of one with an insert following delete with dependent keys under a specific distribution would correspond to the *hold model* proposed in [12] and used in early studies of concurrent priority queues [13, 21]. Choosing large batches would correspond to the sorting benchmark used in [14].

In addition, as in [20] we also evaluated the semantic quality produced by `multiq` and the $k$-LSM with several different relaxations by measuring the rank of items (i.e., their position within the priority queue) returned by `delete_min`. The quality benchmark initially records all inserted and deleted items together with their timestamp in a log; this log is then used to reconstruct a global, linear sequence of all operations. A specialized sequential priority queue is then used to replay this sequence and efficiently determine the rank of all deleted items. Our quality benchmark is pessimistic, i.e., it may return artificially inflated ranks when items with duplicate keys are encountered.

# G.   FURTHER EXPERIMENTAL RESULTS

Each benchmark is executed 30 times, and we report on the mean values and confidence intervals.

Figure 4 shows throughput results for `mars`. Up to 80 threads, each thread is pinned to a separate physical core, while hyperthreading is used at higher thread counts.

Under uniform workload and uniform key distribution, the $k$-LSM has very high throughput, reaching over 300 MOps/s at 80 cores with a relaxation factor of $k = 4096$. For the remaining data structures, `multiq` shows the best performance, reaching around 40 MOps/s at 160 threads (a decrease over the $k$-LSM by around a factor 7.5). The SprayList reaches a maximum of around 11 MOps/s at 140 threads, while the Lindén and Jonsson queue and `global-lock` peak at around 6.7 MOps/s (10 threads) and 7.5 MOps/s (1 thread), respectively.

Varying the key distribution has a strong influence on the behavior on the $k$-LSM. Ascending keys (Figure 4b) result in a significant performance drop for all $k$-LSM variants, all of which behave similarly: throughput oscillates between around 5 and 15 MOps/s until 80 threads, and then slowly increases to a local maximum at around 140 threads. On the other hand, descending keys (Figure 4c) cause a performance increase for the `klsm4096`, which reaches a new maximum of around 400 MOps/s. Behavior of `multiq`, `linden`, and `globallock` remain more or less stable in both cases.

Under split workloads (Figures 4d through 4f), the $k$-LSM's throughput is very low and never exceeds the throughput of our sequential baseline `globallock` at a single thread. Interestingly, the Lindén and Jonsson priority queue has drastically improved scalability when using a combination of split workload and ascending key distribution. We assume that this is due to improved cache-locality: inserting threads access only the tail end of the list, with deleting threads accessing only the list head. `linden` was unstable at higher thread counts under split workload and descending keys, and we omit these results.

A key domain restricted to 8-bit integers (Figure 4g) results in many duplicate key values within the priority queue. This also causes decreased throughput of the $k$-LSM: medium relaxations do not appear to scale at all, while the `klsm4096` does seem to scale well — but only to a maximum throughput of just over 30 MOps/s. The larger 16-bit domain of Figure 4h produces very similar results to the uniform key

benchmark with a 32-bit range.

Hyperthreading is beneficial in only a few cases. For instance, `multiq` makes further modest gains beyond 80 threads with uniform workloads (e.g., Figures 4b and 4g). However, in general, most algorithms do not appear to benefit from hyperthreading.

Table 2 contains our quality results for `mars`, showing both the rank mean and its standard deviation for 20, 40, and 80 threads. In general, the $k$-LSM produces an average quality significantly better than its theoretic upper bound of a rank of $kP + 1$. For example, the `klsm128` has an average rank of 32 under the uniform workload, uniform key benchmark at 20 threads (Table 2a), compared to the maximally allowed rank error of 2561. Relaxation of `multiq` appears to be somewhat comparable to `klsm4096`, and it seems to grow linearly with the thread count. The uniform 8-bit restricted key benchmark (Table 2g) has artificially inflated ranks due to the way our quality benchmark handles key duplicates.

Figure 5 shows results for our AMD Opteron machine called `saturn`. Here, MultiQueue has fairly disappointing throughput, barely achieving the sequential performance of `globallock`, and only substantially exceeding it under split workload and ascending key distribution (Figure 5e). Surprisingly, with keys restricted to the 8-bit range (Figure 5g), the `linden` queue has a higher throughput than all other data structures. Quality trends in Table 3 are consistent with those on `mars`.

Figure 6 and Table 4 display throughput and quality results for `ceres`. On this machine, we display results for up to 4-way hyperthreading. As previously on `mars`, throughput of tested algorithms does not benefit from hyperthreading in general. Only `multiq` appears to consistently gain further (small) increases at thread counts over 64. Split workload combined with uniform key distribution (Figure 6d) causes a local maximum of around 30 MOps/s for the `klsm4096`.

Figure 7 shows throughput results for our Xeon Phi machine `pluto` (there is no corresponding quality table, since we did not run our quality benchmark on this machine). On `pluto`, the $k$-LSM does not match the trend for very high throughput as previously exhibited for the uniform workload and uniform key benchmark (Figure 7a). While scalability is decent up to the physical core count of 61, its absolute performance is exceeded by the `multiq` at higher thread counts. Only in descending key distribution (Figure 7c) does the $k$-LSM reach previous heights. Note that this is also the only benchmark in which throughput on `pluto` exceeds roughly 15 MOps/s. Unfortunately, the $k$-LSM was unstable at higher thread counts under split workloads and we omit all data where it is not completely reliable. Again, hyperthreading results in modest gains for `multiq`, and in stagnant performance for all other data structures in the best case.

Finally, Figures 8 and 9 show results for alternating workloads on all of our machines. Although the alternating workload appears to be similar to uniform workloads (both perform 50% insertions and 50% deletions, and are distinguished only by the fact that operations are strictly alternating in the alternating workload), there are significant differences in the resulting throughput. Uniform keys on `mars` (Figure 8a) show increases for the $k$-LSM in both throughput (to almost 400 MOps/s) and scalability, with all $k$-LSM variants ($k \in \{128, 256, 4096\}$) scaling almost equally well until 80 threads. Likewise, descending keys (Figure 8c) sees all $k$-

LSM variants reaching a new throughput peak of around 600 MOps/s. Behavior on `saturn` is similar, in which uniform and descending keys show improved throughput and scalability for the $k$-LSM, while results for ascending keys remain unchanged from the uniform workload benchmark. On `ceres`, only scalability seems to improve while throughput is again roughly unchanged compared to uniform workload. Finally, on `pluto`, the $k$-LSM surprisingly does not perform well in any case, not even under descending keys (which led to good results when using uniform workload). However, `multiq` throughput increases by almost a factor of 8, reaching over 80 MOps/s in all cases.

In general, the $k$-LSM priority queue seems superior to the other priority queues in specific scenarios: in uniform workload combined with uniformly chosen 32- or 16-bit keys, and with descending key distribution, throughput is almost 10 times that of other priority queues. However, in most other benchmarks its performance is disappointing. This appears to be due to the differing loads placed on its component data structures: whenever the extremely scalable DLSM is highly utilized, throughput increases; and when the load shifts towards the SLSM, throughput drops. The fact that the $k$-LSM is composed of two priority queue designs seems to cause it to be highly sensitive towards changes in its environment.

The MultiQueue does not seem to have the same potential for raw performance as the $k$-LSM at its peak. However, in the majority of cases it still outperforms all other tested priority queues by a good margin. And most significantly, its behavior is extremely stable across all of our benchmark types. Quality results show that relaxation of the MultiQueue is fairly high, but it appears to grow linearly with the thread count.

The `linden` queue generally only scales as long as participating processors are located on the same physical socket; however, a split workload combined with ascending key generation is the exception to this rule, in which the `linden` queue is often able to scale well until the maximal thread count.

(e) saturn, ascending keys.

(f) saturn, descending keys.
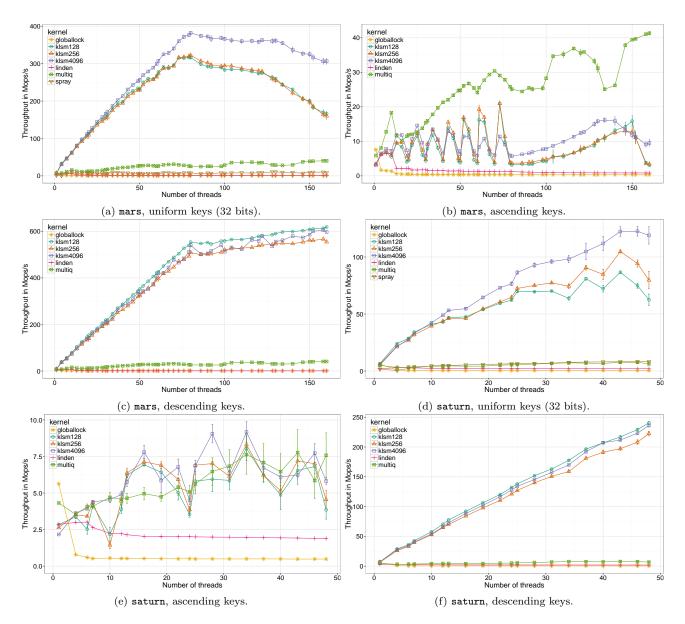

Figure 8: Throughput with alternating workload.

(a) **ceres**, uniform keys (32 bits).

(b) **ceres**, ascending keys.

(c) **ceres**, descending keys.

(d) **pluto**, uniform keys (32 bits).

(e) **pluto**, ascending keys.

(f) **pluto**, descending keys.
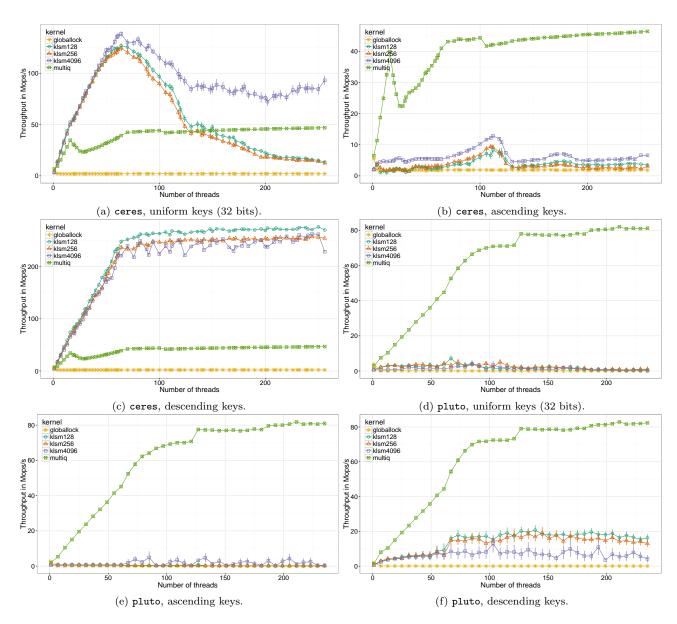

Figure 9: Throughput with alternating workload.

|  | 20 threads | | 40 threads | | 80 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 41 | 39 | 26 | 21 | 443 | 277 |
| klsm256 | 25 | 30 | 43 | 50 | 1377 | 885 |
| klsm4096 | 457 | 726 | 1628 | 1615 | 9486 | 13502 |
| multiq | 1084 | 3243 | 2422 | 8278 | 2890 | 7927 |

(a) mars, uniform keys (32 bits).

|  | 20 threads | | 40 threads | | 80 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 21 | 18 | 22 | 19 | 26 | 22 |
| klsm256 | 38 | 33 | 39 | 34 | 42 | 37 |
| klsm4096 | 495 | 463 | 490 | 464 | 484 | 449 |
| multiq | 100 | 118 | 202 | 238 | 413 | 490 |

(b) mars, ascending keys.

|  | 20 threads | | 40 threads | | 80 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 10 | 7 | 24 | 13 | 40 | 30 |
| klsm256 | 11 | 7 | 23 | 13 | 41 | 28 |
| klsm4096 | 8 | 6 | 20 | 15 | 41 | 36 |
| multiq | 334 | 1634 | 674 | 3640 | 1194 | 4935 |

(c) mars, descending keys.

|  | 12 threads | | 24 threads | | 48 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 17 | 20 | 22 | 23 | 65 | 72 |
| klsm256 | 31 | 39 | 34 | 39 | 115 | 165 |
| klsm4096 | 379 | 599 | 396 | 591 | 915 | 900 |
| multiq | 340 | 839 | 815 | 2178 | 2216 | 6763 |

(d) saturn, uniform keys (32 bits).

|  | 12 threads | | 24 threads | | 48 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 20 | 17 | 21 | 18 | 23 | 20 |
| klsm256 | 37 | 32 | 38 | 33 | 40 | 35 |
| klsm4096 | 509 | 478 | 492 | 467 | 849 | 1402 |
| multiq | 60 | 70 | 120 | 142 | 244 | 287 |

(e) saturn, ascending keys.

|  | 12 threads | | 24 threads | | 48 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 6 | 5 | 11 | 8 | 24 | 16 |
| klsm256 | 6 | 4 | 11 | 7 | 24 | 17 |
| klsm4096 | 5 | 4 | 14 | 10 | 22 | 19 |
| multiq | 182 | 858 | 364 | 1612 | 766 | 3619 |

(f) saturn, descending keys.

|  | 16 threads | | 32 threads | | 64 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 19 | 21 | 30 | 32 | 99 | 129 |
| klsm256 | 30 | 36 | 50 | 71 | 151 | 195 |
| klsm4096 | 355 | 576 | 958 | 1317 | 3602 | 6421 |
| multiq | 1268 | 4727 | 1944 | 6454 | 3433 | 12385 |

(g) ceres, uniform keys (32 bits).

|  | 16 threads | | 32 threads | | 64 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 20 | 17 | 22 | 19 | 25 | 22 |
| klsm256 | 36 | 31 | 39 | 33 | 42 | 37 |
| klsm4096 | 521 | 485 | 491 | 461 | 532 | 491 |
| multiq | 80 | 95 | 163 | 192 | 1049 | 1993 |

(h) ceres, ascending keys.

|  | 16 threads | | 32 threads | | 64 threads | |
|---|---|---|---|---|---|---|
|  | Mean | St.D. | Mean | St.D. | Mean | St.D. |
| klsm128 | 10 | 6 | 16 | 11 | 33 | 23 |
| klsm256 | 9 | 6 | 17 | 11 | 35 | 25 |
| klsm4096 | 9 | 7 | 19 | 15 | 37 | 29 |
| multiq | 280 | 1706 | 551 | 3118 | 1071 | 5497 |

(i) ceres, descending keys.

Table 5: Rank error with alternating workload.
